

# ***Sequence models*** ***(Bernoulli and Markov models)***

# Why do we need random models ?

- Any pattern discovery relies on an underlying model to estimate the random expectation.
  - This model can be simple (succession of independent and equiprobable nucleotides) or more elaborate (differences in oligonucleotide composition).
  - The choice of an inappropriate model can lead to false conclusions.
  - In practice, a sequence model can be used to generate random sequences, which will serve to validate some theoretical assumptions.
- Example: comparison of observed and expected occurrences with the binomial distribution, as applied with oligo-analysis :
  - Relies on an assumption that successive oligonucleotides are independent from each other.
  - This is clearly not the case: each k-letter word depends on the k-1 neighbour words on both sides. How far does it affect the conclusions ?
  - We could test it by generating random sequences, counting words, and fitting the distribution of observed occurrences with a binomial distribution.

# Probability of a sequence segment

- What is the probability for a given sequence segment (oligonucleotide, “word”) to be found at a given position of a DNA sequence ?
- Different models can be chosen
  - **Bernoulli model**
    - Assumes independence between successive nucleotides.
    - The probability of each residue is fixed a priori (*prior residue probability*)
      - Example:  $P(A) = 0.35$ ;  $P(T) = 0.32$ ;  $P(C) = 0.17$ ;  $P(G) = 0.16$
    - Particular case: equiprobable residues
      - $P(A) = P(T) = P(C) = P(G) = 0.25$
      - Simple, but **NOT realistic** !
  - **Markov model**
    - The probability of each residue depends on the ***m*** preceding residues.
    - The parameter ***m*** is called the *order* of the Markov model
    - Remark: a Markov model of order 0 is a Bernoulli model.

- The simplest model : Bernoulli with identically and independently (i.i.d.) distributed nucleotides.

$$p = P(A) = P(C) = P(G) = P(T) = 0.25$$

$$P(S) = p^L$$

- The probability of a sequence

- Is the product of its residue probabilities (independence)
- Equiprobability: since all residues have the same probability, it is simply computed as the residue proba ( $p$ ) to the power of the sequence length ( $L$ )
  - $S$  is a sequence segment (e.g. an oligonucleotide)
  - $L$  length of the sequence segment
  - $p$  nucleotide probability
  - $P(S)$  is the probability to observe this sequence segment at given position of a larger sequence

- Example

- $P(\text{CACGTG}) = 0.25^6 = 2.44\text{e}^{-4}$

## *Bernoulli model : independently distributed nucleotides*

- A more refined model consists in using residue-specific probabilities. The probability of each residue is assumed to be constant on the whole sequence (Bernoulli schema).
- The probability of a sequence is the product of its residue probabilities.
  - $i = 1..k$  is the index of nucleotide positions
  - $r_i$  is the residue found at position  $i$
  - $P(r_i)$  is the probability of this residue
- Example: non-coding sequences in the yeast genome
  - $P(A) = P(T) = 0.325$
  - $P(C) = P(G) = 0.175$
  - $P(CACGTG) = P(C) P(A) P(C) P(G) P(T) P(G)$   
 $= 0.325^2 * 0.175^4$   
 $= 9.91E^{-5}$

$$P(S) = \prod_{i=1}^L P(r_i)$$

# Bernoulli models

- A Bernoulli model assumes that
  - each residue has a specific prior probability
  - this probability is constant over the sequence (no context dependencies)
- The heat-maps below depict the nucleotide frequencies in non-coding upstream sequences of various organisms.
- The frequencies of AT versus CG show strong inter-organism differences.

$$P(r_i | S_{i-m,i-1})$$

- In a Markov model, the probability to find a letter at position  $i$  depends on the residues found at the  $m$  preceding residues.
- The tables represent the transition matrices for Markov chain models of order  $m=1$  (top) and  $m=2$  (bottom).
- Each row specifies one **prefix**, each column one **suffix**.
- The values indicate the probability to observe a given residue (suffix  $r_i$ ) at position ( $i$ ) of the sequence, as a function of the  $m$  preceding residues (the prefix  $S_{i-m,i-1}$ )
- Particular case
  - A Bernoulli model is a Markov model of order 0.

# Markov model estimation (“training”)

- Transition frequencies for a Markov model of order  $m$  can be estimated from the frequencies observed for oligomers ( $k$ -mers) of length  $k=m+1$  in a reference sequence set.
- Example
  - The upper table shows dinucleotide frequencies ( $k=2$ ) computed from the whole set of upstream sequences of the yeast *Saccharomyces cerevisiae*.
  - This table can be used to estimate a Markov model of order  $m = k-1 = 1$ .

# Markov chains and Bernoulli models

- By extension of the concept of Markov chain, Bernoulli models can be qualified as Markov models of order 0 (the order 0 means that there is no dependency between a residue and the preceding ones).
- The prior probabilities of a Markov model of order  $m=0$  can be estimated from the residue of single nucleotides ( $k=m+1=1$ ) in a background sequence set.
- The table below shows the residue frequencies in the genomes of the yeast *Saccharomyces cerevisiae* and the bacteria *Escherichia coli* K12, respectively.
- Notice the strong differences between these genomes.

## Markov order 0 = Bernoulli

A	C	G	T	Genome
0.310	0.191	0.191	0.309	<i>Saccharomyces cerevisiae</i>
0.246	0.254	0.254	0.246	<i>Escherichia coli</i> K12

# Scoring a sequence segment with a Markov model

- Exercise: compute the probability  **$P(S|B)$**  of a sequence segment S with a background Markov model **B** of order 2, estimated from 3nt frequencies on the yeast non-coding upstream sequences.

**S = CCTACTATATGCCCAGAATT**

**Background model B**

# Background sequences

- The frequencies observed for a  $k$ -letter word in a reference sequence set (background sequence) can be used to estimate the expected frequencies of the same  $k$ -letter word in the sequences to be analyzed.
- Typical background models:
  - Whole genome
    - But this will bias the estimates towards coding frequencies, especially in microbial organisms, where the majority of the genome is coding.
  - Whole set of intergenic sequences
    - More accurate than whole-genome estimates, but still biased because intergenic sequences include both upstream and downstream sequences
  - Whole set of upstream sequences, same sizes as the sequences to be analyzed
    - Requires a calibration for each sequence size
  - Whole set of upstream sequences, fixed size (default on the web site)
    - Reasonably good estimate for microbes, NOT for higher organisms.

# Nucleotide composition of the *Plasmodium* upstream sequences

- The genome shows a strong richness in A and T residues (80%AT).
- This enrichment is even stronger in upstream non-coding sequences (86%AT).

## Frequencies

## Upstream frequencies

# Transition frequencies

Markov order  $m=3$   
(based on tetranucleotides  $k=4$ )

- On the basis of oligonucleotide frequencies, one can compute Markov models, which indicate the probability to observe a certain residue (suffix) after a certain oligonucleotide (prefix).
- The Markov model can be represented in the form of a transition table.

Markov order  $m=1$

# Chaos representation - upstream frequencies

- The chaos representation (Jeffrey, 1990) permits to visualize oligonucleotide frequencies and detect enrichment in particular ones.
- Plasmodium upstream sequences are particularly rich for the following motifs
  - A, T nucleotides
  - Oligonucleotides made of As and Ts only (last row of each chaos map)
  - Poly-A and poly-T oligos (bottom corners of the maps)
  - (TA)<sub>n</sub> motifs (the darkest boxes from dinucleotides to tetranucleotides).

Source: Goldman, 1993)

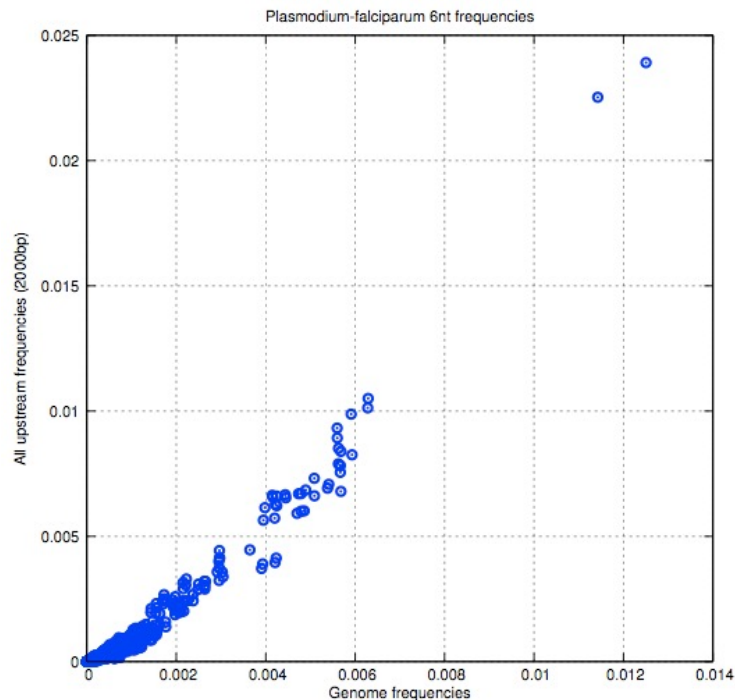

- Goldman. Nucleotide, dinucleotide and trinucleotide frequencies explain patterns observed in chaos game representations of DNA sequences. *Nucleic Acids Res* (1993) vol. 21 (10) pp. 2487-91
- Jeffrey. Chaos game representation of gene structure. *Nucleic Acids Res* (1990) vol. 18 (8) pp. 2163-70

## Hexanucleotide frequencies in *Plasmodium* – Genome versus upstream (2Kb)

- Hexanucleotides show a very wide range of frequencies in the whole genome (X axis) as well as in the subset of upstream sequences (max 2kb, Y axis).
